Hyperthyroidism in Cats

Cats have two thyroid glands, which are located in the neck and play a vital role in regulating the body’s metabolic rate. *Hyperthyroidism* is characterized by the overproduction of thyroid hormone and a subsequent increase in metabolic rate. This disease is common in older cats. Although the thyroid gland enlarges in hyperthyroidism, it is usually a benign or non-malignant change. Fewer than 2% of hyperthyroid cases in cats involve malignant thyroid gland tumors.

Many organs are affected by hyperthyroidism, especially the heart.

**Are certain cats more likely to develop hyperthyroidism?**

Older cats are at greater risk for developing hyperthyroidism. Environmental risk factors have been investigated and may predispose some cats to hyperthyroidism, although the specific mechanisms are not known. Exposure to high levels of dietary iodine may cause susceptible cats to develop hyperthyroidism. No individual breed is known to have a greater risk, although the Siamese appears to have a somewhat increased incidence of hyperthyroidism compared to other breeds.
What are the clinical signs of hyperthyroidism?

"The typical cat with hyperthyroidism is middle aged or older."

The typical cat with hyperthyroidism is middle aged or older - the average age of affected cats is approximately 12 years. Only about 5% of hyperthyroid cats are younger than 10 years of age.

The most common clinical sign of hyperthyroidism is weight loss due to the increased rate of metabolism and despite an increased appetite. Affected cats are often restless, and may become cranky or aggressive. They may have increased water consumption and urination. It is also common for hyperthyroid cats to exhibit increased vocalizing, particularly at night. They may develop periodic vomiting or diarrhea, and fur may appear unkempt. In some cats, anorexia develops as the disease progresses.

Two secondary complications of hyperthyroidism can be significant; Hypertension (high blood pressure) and a particular form of heart disease called thyrotoxic cardiomyopathy. Hypertension develops due to the increased pumping pressure and elevated heart rate that occurs with thyrotoxic cardiomyopathy. About 25% of cats with hyperthyroidism become hypertensive. In some cats, blood pressure can become so high that retinal bleeding or retinal detachment will occur, resulting in sudden blindness.

Thyrotoxic cardiomyopathy may develop because the heart enlarges and thickens to meet the increased metabolic demands. In some cases, the cat will develop a heart murmur associated with the cardiomyopathy. Both the cardiomyopathy and the hypertension are potentially reversible with appropriate treatment of the disease. However, unless the retinal detachment is treated immediately, permanent blindness can occur.

What causes hyperthyroidism?

The exact cause of hyperthyroidism has not been identified, although the role of dietary iodine continues to be investigated as an influencing factor in susceptible cats.

How is hyperthyroidism diagnosed?

"In most instances, diagnosis of this disease is relatively straightforward."

Diagnosis of feline hyperthyroidism is generally straightforward. The first step is to determine the blood level of one of the thyroid hormones, called total thyroxine (or TT4). Usually, the TT4 level is so high that there is no question as to the diagnosis. Occasionally, a cat that is suspected of having hyperthyroidism has a TT4 level within the upper range of normal. When this occurs, a second test, usually either a Free T4 by Equilibrium Dialysis (FT4 by ED) or a T3Suppression Test is performed. If these tests are not diagnostic, a thyroid scan can be performed at a veterinary referral center, or the TT4 can be measured again in a few weeks.
How is hyperthyroidism treated?

Since fewer than 2% of cats with hyperthyroidism have cancerous growths of the thyroid gland, treatment is usually very successful.

Before choosing any form of treatment, several tests are performed which may include blood tests, a urinalysis, chest x-rays, an ECG, and blood pressure measurement. These tests are needed to evaluate the overall health of the cat and to predict the likelihood of complications with the chosen treatment protocol. Cardiac ultrasound or echocardiography may be recommended based on your cat's condition, especially if there is any concern about cardiomyopathy.

"There are four treatment options; anyone of which may be the best choice for a particular patient."

There are three treatment options; any one of which may be the best choice for a particular patient. Many factors must be considered when choosing the best therapy for an individual cat. The four treatment options for hyperthyroidism are:

1. **Medication.** Life-long administration of methimazole can control the effects of an overactive thyroid gland. It takes several weeks for methimazole to restore thyroid hormone levels to normal. Some cats develop side effects to methimazole, which may include vomiting, lethargy, anorexia, fever, liver damage, anemia and a decrease of white blood cells in the blood. In some cases, a decrease in blood platelets (thrombocytopenia) may also occur. Since platelets are important for the clotting of blood, thrombocytopenia may lead to problems with excessive bleeding. Because of these rare but serious side effect risks, your cat will need to be closely monitored by having simple blood tests performed every three to six months when using this drug.

   Methimazole blocks the production of excess thyroid hormone rather than destroying the abnormal thyroid tissue, so the drug must be given for the remainder of the cat's life.

2. **Radioactive iodine.** A very effective way to treat hyperthyroidism is with radioactive iodine therapy (I-131). When an injection of radioactive iodine is given, it destroys the abnormal thyroid tissue without endangering other organs. I-131 therapy does not require anaesthesia, and it eliminates the need for daily medication. Treatment usually requires one or two weeks of hospitalization at a veterinary hospital licensed to administer radiation therapy.

3. **Prescription nutrition.** The most recent development for treating hyperthyroidism in cats is Hills Prescription Diet y/d® Feline. The food is not medicated. Over 10 years of clinical nutrition research revealed that by controlling dietary levels of iodine, the hyperthyroid cat's body would resume normal thyroid hormone production. This is not an iodine-deficient diet. Rather, the iodine content is precisely controlled to 0.32 parts per million – a very small amount!

   For y/d to work, it must be the only food fed, and this means no cheating with treats! When it is the only food offered, y/d is extremely effective, offering an easy, non-invasive, very affordable way to manage feline hyperthyroidism.
Will my cat be cured with treatment?

Recurrence of the disease is a possibility in some cats. Recurrence of hyperthyroidism is rare after I-131 therapy. If methimazole dosing is discontinued, hyperthyroidism will return. Cats fed y/d exclusively will remain normal, but if the diet is discontinued, they will once again become hyperthyroid.

"Recurrence of the disease is a possibility in some cats."

What is the prognosis for hyperthyroidism?

Many owners of cats with hyperthyroidism are hesitant to have radiation therapy because of their cat's advanced age. It is important to remember that old age is not a disease.

"The outcomes following most hyperthyroid therapies are usually excellent..."

The outcomes following most hyperthyroid therapies are usually excellent, and most cats have a very good chance of returning to a normal state of health. Cats managed with diet or medication generally do well as long as their feeding is consistent or their medication is administered routinely and follow-up blood and diagnostic test schedules are performed.

Can hyperthyroidism be prevented?

There are no currently-known preventive measures for hyperthyroidism, but early diagnosis decreases the secondary problems and improves the prognosis. All middle-aged and senior cats should receive a complete physical examination by a veterinarian every six months. Special attention should be given to the thyroid glands, looking for evidence of enlargement and the clinical signs of hyperthyroidism. Annual blood and urine tests are important in all cats over age six to detect hyperthyroidism before potentially irreversible damage occurs.
